Editor: G. Cross
Publisher: Charles Sturt University Press
Pages: 193-202
Keywords: Cholesterolaemia, xanthogranulomatosis
Abstract: This paper describes the clinical case of multiple nodular cutaneous xanthogranulomata located at the right beak commissure and the submandibular space of a 5 year-old female goose. The masses were surgically excised and submitted for histopathological examination. A blood sample taken at the same time as this surgery revealed hypercholesterolaemia and hypertriglyceridaemia. A blood sample taken from a second goose housed with and fed the same diet as the affected goose revealed normal cholesterol and triglyceride levels. Dietary modification and other measures were instigated in an attempt to reduce the triglyceride levels in the affected goose and hopefully prevent the recurrence of the cutaneous xanthomatous neoplasms. These measures resulted in a significant decrease in the levels of cholesterol and triglycerides in the goose. Xanthomatous lesions in association with high blood cholesterol and triglyceride levels have been rarely reported.(1, 2, 3, 4) A very similar case to the one reported here was reported by Jaensch et al.(1, 2) This second case in a goose suggests that the syndrome of persistent hypercholesterolaemia and hypertriglyceridaemia and resultant cutaneous xanthomatous neoplasms may not be an isolated incident and avian veterinarians should be watchful for this clinical picture in geese.

Abstract

This paper describes the clinical case of multiple nodular cutaneous xanthogranulomata located at the right beak commissure and the submandibular space of a 5 year-old female goose. The masses were surgically excised and submitted for histopathological examination. A blood sample taken at the same time as this surgery revealed hypercholesterolaemia and hypertriglyceridaemia. A blood sample taken from a second goose housed with and fed the same diet as the affected goose revealed normal cholesterol and triglyceride levels. Dietary modification and other measures were instigated in an attempt to reduce the triglyceride levels in the affected goose and hopefully prevent the recurrence of the cutaneous xanthomatous neoplasms. These measures resulted in a significant decrease in the levels of cholesterol and triglycerides in the goose. Xanthomatous lesions in association with high blood cholesterol and triglyceride levels have been rarely reported.\(^1, 2, 3, 4\) A very similar case to the one reported here was reported by Jaensch et al.\(^1, 2\) This second case in a goose suggests that the syndrome of persistent hypercholesterolaemia and hypertriglyceridaemia and resultant cutaneous xanthomatous neoplasms may not be an isolated incident and avian veterinarians should be watchful for this clinical picture in geese.

Introduction

In birds, the liver is the principal site of lipid synthesis. In many species of birds, fatty acids not glucose, provides the main energy source, and the avian liver has a very high capacity for lipogenesis.\(^5\) Elevated blood cholesterol levels in birds can be associated with high fat dietary intake, hypothyroidism, liver disease, egg-laying, starvation, diabetes mellitus.\(^6\) Hypertriglyceridaemia in birds is not as commonly reported but can occur in conjunction with egg peritonitis, copper deficiency, in response to oestrogen, cholestasis and familial or idiopathic causes.\(^1, 2, 3, 4, 6\). Persistent hypertriglyceridaemia has been reported to result in xanthoma formation in cats and other species.\(^7\) However, the association of persistent hypercholesterolaemia and hypertriglyceridaemia as a cause of xanthomatous neoplasia in birds has been less frequently reported.\(^8\) There has also been a report of xanthomatosis occurring in commercial chickens attributed to lipid-soluble toxic hydrocarbons in the diet.\(^9\) There has been recent discussion
regarding the classification of xanthomatous lesions in birds, specifically in relation to the
differentiation between the terms xanthoma, xanthomatosis and xanthogranulomatosis. (10) The
multifocal xanthogranulomatosis lesion reported here is consistent with an underlying metabolic
defect of lipid metabolism

Case Report

“LouLou”, an 8.9kg, 5 & 1/2-year-old female goose with a previous history of mild upper respiratory
infections and aggression presented on 23/11/2006 with two xanthomatous, non-painful, semi-
pedunculated masses about 1 cm diameter on the right side of her face near the commissure of the
bill and on the right side of her upper neck as well as thickened pendulous skin in her submandibular
region with a similar 1 cm diameter xanthomatous mass on the cranial pole of this pendulous area.
(Fig. 1). It was noted that she was significantly overweight with excessive subcutaneous and intra-
abdominal fat deposits. Her diet consisted of virtually ad libitum access to grain and poultry layer
pellets as well as daily bread, vegetables, greens and ad libitum access to grass and weeds via free
range grazing. She was also able to regularly gain access to duck layer pellets.
In view of the difficulty that the owners have in transporting LouLou to the clinic it was decided to take a blood sample to analyse her haematology and biochemistry profile and investigate cholesterol and triglyceride levels on the same day of surgical excision of the xanthomatous masses.

LouLou was given 0.8mls of Ketamine (100mg/ml) and 0.65mls of Diazepam (5mg/ml) intravenously via the cutaneous ulnar vein, the intubated and maintained via Isoflurane gaseous anaesthesia. All cutaneous masses were surgically excised as well as resection of the major portion of the abnormal submandibular skin. The skin was sutured with 3/0 Monosyn sutures and the lesions placed in formolsaline for histopathological examination. Blood was taken via the jugular vein for haematological, biochemical (including cholesterol and triglyceride) analyses. LouLou made an uneventful recovery and was sent home with oral meloxicam and amoxicillin-clavulanic acid treatment.

Her blood results were as follows:
Table 1 Haematology and biochemistry parameters measured 23/11/2006 – LouLou

The sample was very lipaemic with no chylomicron layer and the lipid stayed in solution indicating that the fat present was very low density lipoproteins. Lipaemia becomes apparent when the triglyceride levels reach about 3.5mmol/l.

Histological examination of several sections of the biopsied tissue revealed well-vascularised, loosely encapsulated proliferative cellular nodules separated by thin fibro-vascular septae. Larger tumours contained central areas of necrosis. The predominant cell type, particularly at the outer margins of each nodule were relatively well-differentiated foamy histiocytes with abundant cytoplasm containing variable degrees of micro to macrovesicular intracytoplasmic vacuoles. The size of these vacuoles increased further deep into the nodules where there was often a line of demarcation towards the necrotic centre of the larger tumours as cells became degenerate. In such areas there were cells with abundant acicular clefts consistent with cholesterol accumulation. There were coalescing areas of cellular degeneration forming lakes of amorphous pink material most likely rich in lipid and similar areas containing dystrophic calcification. Mitotic figures were rare and when present were in the reactive cell population. There were also mild to moderate multifocal lymphocytic and or heterophbic inflammatory cellular infiltrations without germinal centres also present. (see Figs 2, 3, 4 & 5)
Fig. 2 – Histopathology - Low power view of one xanthomatous nodule beneath skin showing the well vascularised nature (at the margin of the nodule). There is one feather follicle to the right of the section.
Fig. 3 – Histopathology - Higher power showing vacuolated histiocytes and a developing zone of cholesterol clefts (upper right) where cells have degenerated.

Fig. 4 – Histopathology - High power showing vacuolated cells and individual cells with cholesterol clefts.
Fig. 5 – Histopathology - Shows two lymphocytic nodules next to a normal feather follicle. There appears to be a mild perivascular lymphocytic infiltration that in this area has expanded out into 2 relatively large lymphohistiocytic nodules. It is not clear if this is a precursor to the larger xanthomatous tumours or a reaction.
The histopathology appeared almost identical to the case reported by Jaensch et al. (1, 2), however in this case there was more of a multifocal nodular lymphohistiocytic infiltration. The main lesion is composed of large vacuolated histiocytic cells with cholesterol clefts.

Despite the fact that LouLou had been examined and found not to have a phallus, DNA sex determination was also performed on blood taken from LouLou at the time of the surgery and this confirmed that she was female.

A blood sample was also taken from the only other goose housed with LouLou. This goose was a male (“Sam”) and was slightly overweight (7.65kgs) and being offered exactly the same diet as LouLou. His blood results were as follows:

**Table 2 Haematology and biochemistry parameters measured 12/12/2006 – Sam**

The sample showed no lipaemia.

On confirmation of the high cholesterol and triglyceride levels in the blood it was advised that LouLou be put onto a reduced amount of fat and carbohydrate in her diet. Her intake of grain and bread was stopped and the type of layer pellets she received was changed to a type that was lower in energy content. The daily amount of pellets she was offered was also significantly reduced. She
was offered more vegetables and had ad libitum access to grazing. Her level of exercise was also increased.

In consultation with a homeopathic veterinarian, Lou Lou’s owners also gave her the following homeopathic remedies:

1. Thuja 30 C once/week x 6 weeks - apparently this is commonly used for benign growths (especially papillomas) & malignant masses and was used in this case to help prevent re-occurrence after surgery.

2. Nux Vomica LM once /day x 1 month – was used to reduce aggression as Lou Lou became quite aggressive and demanding towards her owners and other waterfowl after her grain access was denied. Nux vomica apparently also has a strong action on liver metabolism and so was used for this purpose given the likelihood of hepatopathy secondary to fat infiltration in this case.

3. Sepia 200 twice/week x 2 weeks – was used to attempt to ameliorate certain behaviours she exhibited such as over-protectiveness and possessiveness of ducklings and a hysterical and highly strung moody nature. During the night, if the ducklings she obsessively protected made any noise, Lou Lou would begin shrieking.

4. One 500 mg fish oil cap/day and 1 teaspoon psyllium husk/day – to attempt to reduce her hypertriglyceridaemia.

On 10/5/2007, approximately 6 months since the surgical excision of the masses, the changes in diet and exercise and the instigation of the homeopathic measures, Lou Lou again presented to the clinic for further examination and repeat blood sampling. At this examination she weighed 7.85kgs, a loss of about 1kg. Her blood results at this time were as follows:

The sample showed no lipaemia.

At the time of this examination there were no further xanthomatous nodular masses anywhere on the body surface but the submandibular region remained slightly pendulous. (see Figs. 6, 7 & 8). Because of ongoing problems with aggression and constant harassment of her owners associated with food and feeding, after reviewing the blood results, Lou Lou was allowed a slightly greater amount of pellets and some access to a small amount of grain in her diet. At the time of writing this paper (2 months after this increase in food access and 7 months after her surgery), Lou Lou still remains free of any further skin masses.

**Fig. 6** Lou Lou 6 months after surgery – note residual pendulous submandibular region and lack of xanthomatous masses

**Fig. 7** Lou Lou 6 months after surgery
Although the histopathological appearance of the lesions in this case very closely resemble those previously reported by Jaensch et al. (1, 2), there were fewer of the nodular masses, they were all restricted to the head and neck regions and no masses were found on the feet. It is postulated that Lou Lou may have been at an earlier stage than the case reported by Jaensch and, given time and no control measures, Lou Lou may have developed more widespread lesions.

The other noteworthy and interesting difference in this case was the response to therapeutic and dietary measures. In the case reported by Jaensch et al, the number and location of the masses meant that complete surgical excision was not possible and a combination of surgery and chemotherapy was attempted. The remaining lesions in that case failed to regress and further lesions developed despite treatment. In the case reported here, there was a significant response to treatment. Surgical excision followed by dietary modification and various homeopathic treatments not only prevented a reappearance of further nodular xanthomatous masses but also significantly reduced the levels of cholesterol and triglycerides in the blood.

Because Lou Lou was clinically normal and had no abnormal haematological and serum biochemistry results, the cause of her persistent fasting hypercholesterolaemia and hypertriglyceridaemia was unlikely to be due to an underlying hepatic or metabolic disease. Based on the response to dietary modification and homeopathic treatments, it is most likely that the cause of Lou Lou’s fasting hypercholesterolaemia and hypertriglyceridaemia may have simply been due to a long term access to a high fat, high energy diet. Obviously not all geese exposed to high fat diets will develop persistent fasting hypercholesterolaemia and hypertriglyceridaemia. Even in this limited trial, two geese exposed to the same diet had significantly different blood cholesterol and triglyceride levels – one markedly elevated and the other within normal ranges. In view of the fact that Lou Lou had never laid an egg and there had been no investigation of thyroid function, it is possible that there may have been some hormonal influence on her cholesterol and triglyceride levels. This could explain the difference between the responses of the two geese in this case after exposure to the same diet. Alternatively, there may be a familial or idiopathic explanation of Lou Lou’s abnormally high cholesterol and triglyceride levels.
Although not proven here, it is postulated that persistent hypercholesterolaemia and hypertriglyceridaemia was the cause of the cutaneous xanthomatous neoplasms in this case and in the Jaensch et al case and it is interesting that both of these cases involve geese. It is possible that some geese may develop cutaneous xanthogranulomata if exposed to high blood cholesterol and triglyceride levels for a long enough period of time, regardless of the cause of those high blood levels. It is recommended that a full blood biochemical investigation (including cholesterol and triglyceride levels) be performed on any bird presenting with multiple xanthomatous masses.
