Introduction

In Australia, the farming and scientific community have relied very heavily on the results of soil testing to indicate whether a pasture paddock is likely to be responsive to the application of fertiliser. In pastures with a reasonable legume content, it is generally phosphorus and sulphur that limit pasture productivity (Whittet 1925, Donald 1965, Henzell 2007). Various models have been developed over time that predict the optimum soil available phosphorus level where pasture production is unlikely to be unlimited. Refinements to these models have been made recently which take into account the phosphorus buffering index (PBI) and animal removal of nutrients from the pasture system (Gourley et al. 2007, Simpson et al. 2009). Such refinements are an important step in better matching fertiliser input requirements to pasture needs. Improved targeting of fertiliser use is becoming increasingly important with the rising cost of fertiliser and predictions that phosphorus based fertiliser prices will double again within the next 10-15 years (van Kauwenbergh 2010). While recent refinements to phosphorus requirement models are an important step in increasing the efficiency with which this resource is used, these models still assume uniformity in response to application of fertiliser. That is, there is little capacity of these models to take into account variation in landscape characteristics such as soil depth, moisture holding capacity and aspect; all of which can affect botanical composition and therefore the ability of pasture to respond to fertiliser addition. Simpson et al. (2009) has factored in some landscape characteristics of slope and its effect on nutrient loss into a phosphorus requirement model, but this is based on New Zealand data. More fundamentally, all phosphorus requirement models are based on the ‘basal nutrient’ type of approach to determining phosphorus requirement. The historical method of determining critical nutrient levels has been to apply all nutrients except the nutrient of interest (in this case, phosphorus) to a level where they will not limit pasture production. The nutrient of interest is then added at incremental rates to determine a response curve for that nutrient. While such an approach is scientifically valid, it is not a practice that can be undertaken at a broad scale in a farming situation. Further, traditional fertiliser requirement experiments generally occurred in botanically favourable well-balanced pastures where topography was not variable. How applicable then are such results in pasture paddocks where topography, soil type and pasture composition vary?

There have been many experiments undertaken in variable landscapes in New Zealand to determine the extent of variation in pasture production and in many cases, response to fertiliser in topographically diverse landscapes (Radcliffe 1982, Gillingham et al. 1999).
Similarly, studies have been undertaken to determine the impact of adopting a strategic approach to fertiliser application in these landscapes, which considers landscape features and response potential. Such changes in management have revealed considerable benefits to overall farm profitability by adopting such management changes. To date, there has been very little research in Australia to determine how variable pasture production and response to fertiliser is in topographically diverse pasture paddocks. Some preliminary research by Hackney and Virgona (2001) demonstrated pasture production ranged from 300-9000 kg DM/ha in a topographically variable pasture paddock on the south-west slopes of NSW. Such differences in production potential indicate that the assumption of uniformity of pasture production and therefore response potential to applied fertiliser is likely to be flawed. The remainder of this paper reports on the results of a fertiliser response studies on the Central Tablelands and Monaro regions of NSW in variable landscape paddocks.

Research site locations and design
Two sites were chosen, one on the Central Tablelands at Burraga approximately 80 km south of Bathurst and the second at Jimenbuen on the Monaro approximately 60 km south-west of Cooma. At each of these sites, fertiliser experiments were located at upper and lower slope positions on a north and south aspect (referred to as north upper (NU), north lower (NL), south upper (SU) and south lower (SL)). At each position in the landscape, single superphosphate was applied at rates equivalent to 0, 10, 20, 40, 60 and 80 kg P/ha each year for three years. The long-term annual rainfall at the Burraga site was 830 mm. Over the years of the experiment (2001-2003) rainfall was 89%, 77% and 87% of the long term average. At Jimenbuen the long term average rainfall was 560 mm and over the years of the experiment it was 110%, 95% and 84% of the long term average.

The sites chosen were native perennial grass based pastures typical of those found in each respective region. The Central Tablelands site was a microlaena (Microlaena stipoides) based pasture while the Monaro site was a spear grass (Austrostipa bigeniculata) based pasture. At both sites, subterranean clover (Trifolium subterraneum) had been introduced in the past during the sub-super era of pasture improvement. Varieties of subterranean clover present at the sites included Mt. Barker and Woogenellup. Both sites were acidic with pH at the Burraga site ranging from 4.4-4.8 across landscape positions. At Jimenbuen pH ranged from 4.6-4.8 across landscape positions. Aluminium as a percentage of total cation exchange capacity ranged from 8-22% across landscape positions at the Burraga site and from 4-10% at the Jimenbuen site.

Pasture composition and herbage was assessed using the botanal technique (Tothill et al. 1992) 15 times at the Burraga site over three years and 14 times over three years at the Jimenbuen site. Herbage was cut and removed after each assessment.

Results
While the pasture paddocks used in this study would generically be considered native perennial grass-annual exotic legume-based, the composition differed across the sites
significantly at the commencement of the study (Table 1). In general, the legume component of the pasture was significantly lower on north aspect positions. At the Burraga site, the native grass frequency was significantly lower at the NU position compared to all other positions in the paddock. At Jimenbuen, the highly drought tolerant spear grass was present at higher frequency on the north slope while remnant cocksfoot (*Dactylis glomerata*), a result of pasture sowing in the 1970’s, were found only at south slope positions.

**Pasture production and fertiliser response**

Over the three years of the study, cumulative pasture production ranged from 18.4-31.7 t DM/ha at Burraga and 15.8-19.8 t DM/ha at Jimenbuen respectively (Figure 1). At both sites, south slope positions in the landscape were significantly more productive than those on the north slope without addition of fertiliser. Legumes contributed significantly more to overall pasture production on the south compared to slopes of both the Burraga and Jimenbuen sites without addition of fertiliser (Hackney 2009).

Despite all positions at both sites having soil available P levels which would indicate they should be responsive to phosphorus application, only three of the four positions at the Burraga site showed increases in pasture production with addition of fertiliser (Figure 1) while at Jimenbuen, only one of the four positions was responsive to application of fertiliser.

At the Burraga site, where responses to application of phosphorus were found, the response was due solely to an increase in legume production while at Jimenbuen the increase was due to a combination of increased production from legumes and from cocksfoot (data not shown). The increase in pasture production at the Burraga site occurred in spring of all three years and in autumn in the final year of the study. At Jimenbuen, increase in pasture production with use of fertiliser occurred only in spring and only in the first year of the study where seasonal conditions were wetter than average.
Figure 1. Cumulative herbage production over three years at north upper (NU), north lower (NL), south upper (SU) and south lower (SL) slope positions at various rates of phosphorus application (applied as single superphosphate) at Burraga (a) and Jimenbuen (b).

Why is pasture production and composition so variable and why were some positions unresponsive to fertiliser application despite having low initial available soil P?
Solar radiation was measured on the north and south slope at both sites. Solar radiation over the period of the study was 8% and 5% greater on the north compared to the south slope at the Burraga and Jimenbuen sites respectively. This difference in solar radiation may not seem like a lot, but it equates to a difference of 5.2° and 3.9° of latitudinal displacement between the north and south facing slope for the Burraga and Jimenbuen sites respectively. As a result of this, soil temperature was generally higher at north slope positions. While it might seem that higher soil temperatures would be more favourable for pasture growth, it also means that soils dry out more quickly. At the north slope positions, measurements taken over the duration of this study showed that these landscape positions were either consistently drier and/or had more erratic wetting and drying patterns meaning that sustaining long periods of pasture growth is less likely. Consistency of moisture availability is particularly important for shallow rooted species such as the annual legumes found at these sites. At both Burraga and Jimenbuen, annual legumes contributed more to overall pasture production on the south slope positions without fertiliser addition than on the north slope positions and it is likely that the less consistent soil moisture conditions had contributed to lower populations of legumes at north slope positions. Despite both paddocks having had subterranean clover sown introduced uniformly across the paddocks, populations were lower on the north slope, particularly at Jimenbuen than on the south slope. Similar results have been reported in New Zealand studies. An adequate legume population is essential in realising an increase in pasture production in response to phosphorus fertiliser addition. Grasses will respond to application of phosphorus fertiliser, but only up to the limit of nitrogen available to them in the soil.

Nutrient responsive locations had moderate to high initial populations of legumes (Table 1). However, legume content alone did not indicate whether or not a location would be responsive to addition. The SL position at the Burraga site had good legume content but did not respond to fertiliser addition. This location, however, did have the highest level of exchangeable aluminium. Evans et al. (1988) reported decline in subterranean clover herbage production when exchangeable aluminium exceeded 15% of total cation exchange capacity. At the SL position at the Burraga site the exchangeable aluminium content at the commencement of the study was 22%. High levels of aluminium impact directly on root development preventing cell division at the root tips resulting in stunting of the root system. This in turn affects the ability of the plant to harvest nutrients and moisture thereby restricting growth. Further, low pH – high exchangeable aluminium soils reduce the survival of the rhizobia responsible for nodulation of subterranean clover (Munns 1968, Burnett et al. 1994). Without adequate nodulation, legumes fail to fix nitrogen for use by non-leguminous pasture plants and therefore there is limited capacity to respond to applied phosphorus. It is possible that high levels of aluminium affected legume growth at the SL position at the Burraga site and therefore restricted response to application of phosphorus fertiliser. Interestingly though, an additional fertiliser treatment consisting of lime (2.5 t/ha) applied in combination with 80 kg P/ha did not significantly increase overall total pasture production or total legume production compared to the nil phosphorus treatment. Another possibility is that under low pH-high exchangeable aluminium conditions at the SL position, rhizobium survival had declined over time resulting in poor or ineffective nodulation of the subterranean clover and...
therefore limited nitrogen fixation which restricted nitrogen available to non-leguminous pasture components and limited ability to respond to applied phosphorus.

**What are the implications of the findings of this study for fertiliser management in the future?**

This study has found that pasture response to fertiliser application in variable landscapes differs significantly. In the paddocks used in this study, previous management had attempted to create greater uniformity in pasture composition through the introduction of annual legumes and at Jimenbuen, through the sowing of the perennial grass cocksfoot. Over the intervening period since the legume and/or perennial grass introductions, pasture composition had diverged resulting in distinctly different pasture communities based either on an aspect or within aspect basis. This was most apparent at the Jimenbuen site where cocksfoot, 30 years after being sown, was found only on the south facing aspect and subterranean clover populations were higher on the south than the north facing aspects. Differences in microclimate, particularly moisture availability, or more specifically the consistency of moisture availability have probably been partially responsible for the differences observed in current plant communities across the sites. Overlaying this of course is the impact of grazing. In landscapes such as those used in this study, it is difficult to manage grazing for uniformity of pasture utilisation. Thus, areas of such paddocks may be under or over-utilised which, over time results in plants tolerant of heavy grazing (those with low growing points and/or short lifecycles) dominating in heavily grazed areas while different communities are formed in less utilised areas. The results presented here show that predicting fertiliser responses is problematic unless other factors are taken into account. How then do we attempt to best manage these landscapes?

In terms of managing fertiliser application, the results of this study have identified key parameters which will assist in identifying areas capable of responding to phosphorus fertiliser addition:

1. Assess any physical soil limitations in the landscape – this will involve looking at soil depth and soil texture. Deep soils are capable of maintaining longer periods of pasture growth as they have the capacity to hold more moisture than shallow soils. Similarly, coarse textured soils will have less capacity to hold moisture than those with a finer texture. Assess whether the soil at different points in the landscape have any other physical limitations. For example, are there areas of landscape where the soil becomes waterlogged. If so, such soils may be as limited in productive capacity as a soil that is shallower and of coarser texture depending on how long the period of waterlogging persists.

2. Assess the current composition of the pasture – it is particularly important to be able to assess the legume content of the pasture. If legume content is lacking at specific areas in the landscape, then the capacity of that area to respond to application of phosphorus fertiliser will be limited. Certainly, botanical composition can be altered to some extent, for example, by introducing legumes into legume deficient pastures. However, assessment of pastures in their current
state will give a good indication how position in the landscape has influenced the pasture composition. This may also give you an indication of how successful introducing species such as legumes into the landscape may be. For example, if you assess an area and find that it is a shallow soil and coarsely textured, then its ability to hold sufficient moisture to sustain long periods of pasture growth will be limited and investing heavily to alter pasture composition in an attempt to illicit a fertiliser response may be of questionable value.

3. Assess possible soil chemical limitations at locations in the landscape with favourable soil physical and botanical composition characteristics – often this is the first component considered in deciding whether or not to apply fertiliser to a pasture. However, unless soils have the ability to maintain good levels of moisture for prolonged period and thus support a pasture with composition capable of responding to fertiliser application, then the worth of applying fertiliser needs to be questioned. It is also important to look further at soil tests than simply the level of available phosphorus. In many tableland soils, aluminium toxicity is common. Where levels of exchangeable aluminium exceed 15% it is likely that subterranean clover production is being restricted either through root stunting and/or by reduced survival of rhizobia and therefore reduced nodulation and nitrogen fixation. There may be capacity to address surface acidity/aluminium toxicity through surface application of lime, however, be aware that the rate of amelioration using surface application is slow in comparison to incorporation. Additionally, consideration may need to be given to the reintroduction of rhizobia as it may have been reduced to negligible levels in the previously low pH – high aluminium conditions. Results from Western Australia have shown significant increases in old established subterranean clover pastures where rhizobia levels are deliberately increased through addition of inoculant. Assessment of current rhizobia levels and their efficacy in old subterranean clover based pastures is an area requiring research in NSW.

If the three factors above are considered, then it may be possible to implement a differential approach to fertiliser application – applying fertiliser only to areas with good moisture holding capacity and botanically favourable composition. Certainly, such an approach can significantly reduce expenditure on fertiliser – an important consideration for future farming practices, given the predicted increase in world fertiliser prices (van Kauwenbergh 2010). However, how effective such an approach will be in isolation will depend on the ability to utilise the additional pasture growth achieved. In highly variable landscapes, livestock can be highly preferential in their grazing habits and the period of time they spend in specific areas of the landscape can be greatly influenced by weather conditions, as well as the species and breed of the grazing animal. Ultimately, the relative success, economic and/or environmental, of adopting a differential approach to input management, particularly with regard to fertiliser use, will depend on the ability to control grazing behaviour. That is, there will need to be sufficient subdivisional fencing to allow appropriate grazing management and utilisation of additional herbage produced.
